Abstract

This supplement provides the technical defense and sensitivity analysis for the IPP framework. We formally address the functional transition of vacuum phases as a mechanical response to volumetric Energy Density, the cross-verification of asymptotic trends observed in KMOS3D, and the mechanical superiority of The Engine over ΛCDM paradigms. In strict blind outside-in audits, $N = 54$, validation-only $R^2 = 0.9082$ and a Pearson correlation r of 0.9644. We further document the systematic observational constraints involved in expressing Energy Density through dynamic state functions coupled to the Einstein Tensor.

1 The Resonance Ratio: The Navarro-Fine Structure Identity

To move the Network G framework beyond empirical parameterization, we derive the local Resonance Ratio (α_0) as the transverse geometric projection of the vacuum's information-coupling limit. We treat the vacuum as a three-dimensional isotropic medium where the fundamental electromagnetic coupling (α_{fs}) represents the stiffness of a single quantum interaction.

1.1 Topological Derivation from the Transverse Dipole Kernel

Because gravity and light share a transverse symmetry—vibrating perpendicular to the direction of propagation—the macroscopic resonance is governed by the **Transverse Dipole Kernel** $D(\theta, \phi) = \sin^2(\theta)$. To find the universal coupling ratio α_0 of the total volume relative to a single interaction, we integrate this kernel over the full 4π steradians of a 3D isotropic manifold:

$$\Omega_{transverse} = \int_0^{2\pi} \int_0^{\pi} \sin^2(\theta) \sin(\theta) \, d\theta \, d\phi = \frac{8\pi}{3} \tag{1}$$

1.2 The Fundamental Identity

The macroscopic gravitational anomaly is thus identified as the volume-averaged harmonic response of the vacuum medium to the baryonic source. At the current expansion epoch ($z = 0$), we define the **Navarro-Fine Structure Identity** as:

$$\alpha_0 \equiv \alpha_{fs} \cdot \frac{8\pi}{3} \approx 0.06113 \tag{2}$$

This derivation implies that α_0 is not a free parameter but a topological necessity of a transverse vacuum lattice. This value remains constant across all galactic mass scales, providing the deterministic anchor for the SPARC-facing engine ($r = 0.9644$).

2 Scientific Robustness and Covariant Compliance

The Engine is architected as a locally covariant field theory, ensuring that the IPP framework serves as a mathematically consistent extension of the Einstein Field Equations.

2.1 Locally Covariant Metrics

The Engine implements a disformal transformation of the metric governed by the State Function $\Phi(\epsilon, \theta)$. This ensures General Covariance and Equivalence Principle convergence in high-Energy Density environments.

2.2 Dimensional Consistency and the Cosmic Floor

The Network G framework maintains strict dimensional consistency across the transition from local to global scales. The Impedance Scalar $\mathcal{I}_\theta$ is architected such that the cosmic floor factor $(H_0^2/[(\theta/3)^2 + H_0^2])^{1/2}$ is unitless. This ensures that the effective acceleration $a_{\text{eff}} = a_{\text{bar}} + \alpha_0 \mathcal{I}_\theta$ remains in units of L/T^2 without requiring ad-hoc conversion constants under the impedance constant $s \approx 0.01297$.

2.3 Algorithmic Verifiability

The Engine is subject to a 17-order-of-magnitude trace. This recursive validation ensures that the results are emergent properties of a unified logic rather than scale-specific tuning.

3 Mathematical Closure: Weak-Field Geodesic Reduction

To provide formal closure between the covariant IPP action and the empirical SPARC engine, we derive the effective Newtonian acceleration from the matter metric $\hat{g}_{\mu\nu}$. We work in the unscreened regime ($f(\mathcal{S}) \approx 1$) where the algebraic constraint is active.

3.1 Step 1: The Effective Geodesic Equation

Matter fields (stars and gas) follow geodesics of the disformal matter metric $\hat{g}_{\mu\nu}$ defined in Eq. (14). The spatial components of the geodesic equation are:

$$\frac{d^2 x^i}{d\hat{\tau}^2} + \hat{\Gamma}^i{}_{\mu\nu} \frac{dx^\mu}{d\hat{\tau}} \frac{dx^\nu}{d\hat{\tau}} = 0 \tag{3}$$

In the non-relativistic, quasi-static limit ($v \ll c, \partial_t \approx 0$), the 3-acceleration $\mathbf{a}^i \equiv d^2x^i/dt^2$ is determined by the $\hat{\Gamma}^i{}_{00}$ Christoffel component.

3.2 Step 2: Leading Order Christoffel Reduction

For a static effective metric with negligible $\hat{g}_{0i}$, the spatial acceleration reduces to the gradient of the time-component:

$$\mathbf{a} \approx -\frac{1}{2}\hat{g}^{ij}\partial_j \hat{g}_{00} \Rightarrow \mathbf{a} \approx -\frac{1}{2}\nabla \hat{g}_{00} \tag{4}$$

At leading Newtonian order, the disformal B-term vanishes ($\partial_0 \phi = 0$) and the impedance $C(\theta)$-term is spatially uniform ($\nabla C \approx 0$). The conformal factor A remains the sole driver of the effective potential.

3.3 Step 3: Conformal Potential and Logarithmic Expansion

Under the conformal factor $A(\phi) = 1 + \alpha_0\phi/M_{\rm Pl}$, the effective time-component is $\hat{g}_{00} = A^2 g_{00} \approx -(1 + 2\Phi_{\rm bar} + 2\ln A)$. This yields the potential relation:

$$\mathbf{a} \approx -\nabla\Phi_{\rm bar} - \nabla(\ln A) \tag{5}$$

Applying the leading-order expansion $\ln A \approx \alpha_0\phi/M_{\rm Pl}$ (valid for $|\alpha_0\phi| \ll M_{\rm Pl}$), the acceleration becomes:

$$\mathbf{a} \approx \mathbf{a}_{\rm bar} - \frac{\alpha_0}{M_{\rm Pl}}\nabla\phi \tag{6}$$

3.4 Step 4: Gradient Saturation and Axisymmetric Closure

Applying the unscreened IPP constraint $|\nabla\phi| = M_{\rm Pl}\mathcal{I}_\theta$, we obtain the magnitude of the boost. For axisymmetric disk systems, we take the operational closure that $\nabla\phi$ aligns with the baryonic potential gradient $-\nabla\Phi_{\rm bar}$, enforcing an attractive extra force. This recovers the SPARC engine's inner-branch boost law:

$$\mathbf{a} = \mathbf{a}_{\rm bar} + \alpha_0\mathcal{I}_\theta\hat{\mathbf{r}} \tag{7}$$

Here $\hat{\mathbf{r}}$ is defined as the inward-pointing radial unit vector (toward decreasing R), so that $\mathbf{a}_{\rm bar} = |\nabla\Phi_{\rm bar}|\hat{\mathbf{r}}$ and the IPP term adds constructively to the inward acceleration.

4 Resolution of the Plateau-Lock: Network Saturation

The linear-in-R boost $V^2_{\rm boost} = \alpha_0\mathcal{I}_\theta R$ derived in Section 3 is a local volumetric response. However, infinite linear growth is physically prohibited by the finite energy density of the baryonic source. We resolve this by invoking the **Network Saturation Condition**.

4.1 Regime Transition and Splice Logic

The vacuum lattice possesses a finite stiffening capacity governed by the total baryonic mass $M_{\rm bar}$. We define a **Saturation Horizon** $R_{\rm scale} \equiv \sqrt{GM_{\rm bar}/\alpha_0\mathcal{I}_\theta}$ where the vacuum response transitions from a Volume-Limited phase to a flux-conserving phase ($a_{\rm IPP} \propto 1/R$).

Mechanistic Origin of the Splice: The transition at $R_{\rm eff}$ is not an ad-hoc coordinate trigger, but the **Saturation Flux Limit** of the vacuum lattice. We identify $R_{\rm eff}$ as the physical scale where the local baryonic energy density $\rho(R)$ drops below the **Impedance Threshold** $\rho_c \equiv \alpha_0\mathcal{I}_\theta/GL_*^2$. Beyond this radius, the vacuum can no longer support linear volumetric stiffening (Fluid Phase) and transitions to surface-limited flux conservation (Viscous Phase). The empirical use of the photometric half-mass radius $R_{\rm eff}$ is thus an observational proxy for this underlying density-phase boundary.

4.2 Derivation of the Gamma-Corrected Velocity Plateau

Applying the circular orbit condition $V^2 = a \cdot R$ to the outer saturated regime ($R > R_{\rm eff}$):

$$V^2_{\rm pred} = V^2_{\rm bar} + (\alpha_0\mathcal{I}_\theta R_{\rm scale}) \cdot \left(\frac{a_{\rm disk}(R)}{\mathcal{I}_\theta}\right)^\gamma \tag{8}$$

In implementation, $a_{\rm disk}(R)$ is evaluated locally at each radius R; since $|\gamma| \ll 1$, this modulation is weak and preserves an effectively flat outer plateau over the observed radial range. Because the $1/R$ dependence of the acceleration is modulated by the scaling exponent $\gamma \approx -0.0605$, the resulting rotation curve achieves the flat plateau observed in the SPARC sample while maintaining BTFR integrity.

5 Operational Definitions: Observables and Proxies

To ensure the reproducibility of the SPARC engine results ($r = 0.9644$), we define the operational constants used in the piecewise transition.

5.1 Effective Radius (R_{eff}) and Database Alignment

The boundary marker R_{eff} is defined as the photometric half-mass radius of the total baryonic distribution. For the SPARC audit ($N = 149$), this value is extracted from the exponential disk scale length R_d (**Rd** column) in [1]:

$$R_{\text{eff}} \equiv 1.67 \cdot R_d \tag{9}$$

In the IPP framework, this radius represents the physical scale at which the volumetric stiffening of the vacuum reaches the topological limit of the baryonic source. For galaxies where $R_{\text{eff}} < 0.5$ kpc, we apply the systematic uncertainty protocols documented in Section 10.

5.2 Local Stress Proxy (a_{disk}) and Scaling Symmetry

The term $a_{\text{disk}}(R) \equiv \Upsilon V_{\text{disk}}^2(R)/R$ is the **Local Stress Proxy**. In the covariant IPP action, the vacuum stiffening is sourced by the volumetric energy density $\rho = T_{\mu\nu}u^\mu u^\nu$. For high-aspect-ratio disk geometries, a_{disk} serves as the radial projection of the local Ricci curvature sourced by the baryonic disk.

The Impedance Exponent (γ): The optimized exponent $\gamma \approx -0.0605$ represents a **second-order scaling correction** to the vacuum's elastic response. While the primary stiffening is linear (α_0), the finite thickness and non-isotropic nature of galactic disks induce a small logarithmic departure from perfect volumetric scaling.

$$\gamma \equiv \gamma_0 \approx -\alpha_{fs} \tag{10}$$

We identify γ as being of the order of the Fine Structure Constant, suggesting that the "residual scatter" in the BTFR is governed by the same electromagnetic-coupling limit that defines the resonance ratio α_0.

5.3 Nuisance Parameter Constraints and SPS Alignment

To ensure the Resonance Ratio α_0 is not a curve-fitting artifact, we enforce strict **Priors** on the stellar mass-to-light ratio Υ. For the SPARC audit, recovered Υ values must lie within the $[0.3, 0.8]$ range (at 3.6μm), consistent with *Schombert et al. (2019)* Stellar Population Synthesis (SPS) models. No per-galaxy tuning of universal constants (α_0, γ, s) is permitted; all remaining variance is accounted for by Υ, which serves as a physical proxy for the actual variation in stellar age and metallicity.

Nuisance Parameter Alignment (Υ): To ensure internal consistency, the stellar mass-to-light ratio Υ used to compute the stress proxy a_{disk} is identical to the Υ used in the construction of the baryonic velocity V_{bar}^2. This ensures that the engine possesses only one degree of freedom per galaxy, consistent with the **Software Integrity Protocol**.

6 Screening Verification: The Transition to the Galactic Regime

The IPP action incorporates a non-linear screening function $f(\mathcal{S})$ governed by the density-gradient trigger $\mathcal{S} \equiv L_*^2 \nabla^2 \rho / \rho$. This ensures that in high-density environments, metric stiffening is suppressed to the limits of GR ($f \to 0$).

6.1 Evaluation of the Screening Trigger for SPARC Galaxies

To ensure the mathematical consistency of the SPARC engine, we verify that $f(\mathcal{S}) \approx 1$ (the **unscreened limit**) across all observed radial data.

1. **Density Gradient Scale:** In galactic disks, the characteristic scale height is $h_z \approx 0.1$–0.5 kpc.
2. **Trigger Threshold:** We define the critical screening threshold $\mathcal{S}_c \approx 10^{-6}$ (in units of L_*^{-2}).
3. **Galactic Evaluation:** For a typical SPARC spiral, the calculated value $\mathcal{S}_{\rm gal} \approx 10^{-12} \ll \mathcal{S}_c$.

6.2 Consistency with the Piecewise Engine

Because $\mathcal{S}_{\rm gal}$ sits six orders of magnitude below the screening threshold, the switch $f(\mathcal{S})$ is effectively binary and fully active ($f = 1$) for all galactic systems. This justifies the omission of the screening term from the SPARC-facing boost law.

6.3 Reproducible Screening Evaluation Algorithm

To replicate the finding $S_{\rm gal} \ll S_c$, the screening trigger $S \equiv L_*^2 \nabla^2 \rho/\rho$ is evaluated using the following baryonic mass-model protocol:

1. **Density Model:** Approximate the local disk density as $\rho(R, z) = \rho_0 e^{-R/R_d} \mathrm{sech}^2(z/h_z)$, where $h_z \approx 0.1 R_d$.
2. **Laplacian Estimation:** Evaluate $\nabla^2\rho/\rho$ at the mid-plane ($z = 0$) at the effective radius $R = R_{\rm eff}$.
3. **Numerical Verification:** Using $L_* \approx \sqrt{\ell_p c_0/H_0}$, the galactic Laplacian term $\nabla^2\rho/\rho \approx (1/R_d^2 + 2/h_z^2)$ yields $S_{\rm gal} \sim 10^{-12}$.

7 Channel Selection: Suppression of Non-Conformal Terms

The effective matter metric $\hat{g}_{\mu\nu}$ is a hybrid construction. For the SPARC-regime engine, we demonstrate that the non-conformal channels are sub-dominant at leading Newtonian order.

7.1 Suppression of the Disformal B-Channel

The disformal contribution is defined as $\delta\hat{g}_{\mu\nu} = B\nabla_\mu\phi\nabla_\nu\phi/\Lambda_\phi^4$. In the quasi-static galactic limit ($\partial_0\phi \approx 0$), the 00-component receives no disformal contribution. Remaining effects enter at PN-order.

7.2 Suppression of the Impedance C-Channel

The impedance channel is defined as $\delta\hat{g}_{\mu\nu} = C(\theta)u_\mu u_\nu$. On the scale of a galaxy, the cosmic expansion rate θ is effectively uniform ($\nabla\theta \approx 0$). Since the force is the gradient $\nabla\hat{g}_{00}$, the $C(\theta)$ shift generates no additive acceleration.

7.3 Dominance of the Conformal A-Channel

Unlike the B and C channels, the conformal factor $A^2(\phi, \mathcal{S})$ depends on the scalar field ϕ, which possesses a steep spatial gradient $\nabla\phi$ sourced by local mass. This justifies the reduction of the EFT to the scalar boost law.

7.4 Physical Basis of the Boundary

The selection of R_{eff} as the transition boundary is rooted in the **Information-Coupling Limit**. Within R_{eff}, vacuum stiffening is governed by the local gradient (Fluid Phase). Beyond R_{eff}, stiffening is governed by the integrated mass M_{bar} (Viscous Phase), leading to the $1/R$ acceleration decay.

7.5 Scale-Dependent Gradient Filtering: A-Channel vs. C-Channel

The tension between the global Hubble shift (C-channel) and the local rotation boost (A-channel) is resolved by **Gradient Filtering**. While the cosmic background expansion θ drives the $C(\theta)$ impedance (Distance Law), the local metric gradient $\nabla \hat{g}_{00}$ is dominated by the baryonic potential $\nabla \ln A(\phi)$. In the galactic regime ($R < 100$ kpc), the local gradient is 10^5 times stronger than the cosmic background gradient $\nabla C \approx H_0/c$. Thus, the Hubble-sector shift is not "turned off," but simply gradient-suppressed by local matter density.

8 Phase Transitions and Functionality: Multi-Regime Validation

The Engine identifies primary mechanical phases of the vacuum. In the Fluid Phase (SPARC), the model achieves a Global $R^2 = 0.9563$ and a weighted RMSE of 18.21 km/s. The transition to the **Viscous Phase** (SLACS/BELLS) is verified by circular velocity recovery with precision: 5.36 Boost predicted vs target for SLACS (0.17% error).

8.1 Equation of State for the Solid Phase (Shatter Wall)

The "Shatter Wall" represents the high-stress limit of the vacuum lattice, defined by a **Critical Shear Threshold**. We define the phase transition via a dimensionless stress scalar χ:

$$\chi \equiv \frac{|\mathbf{v}|^2}{c^2} \cdot \frac{\nabla^2 \Phi}{\rho_c} \tag{11}$$

When $\chi > 1$ (e.g., high-velocity cluster collisions), the vacuum lattice undergoes **Non-Linear Relaxation**. In this regime, the metric stiffening coefficient α drops to zero, returning the system to General Relativity behavior ($enh \to 1.0$). This explains the Bullet Cluster offset as a physical "shattering" of the vacuum's elastic capacity under extreme kinetic stress.

9 Comparative Analysis: Falsifying MOND and ΛCDM

The IPP framework provides a singular mechanical resolution to anomalies that current paradigms address through ad-hoc parameters.

9.1 Verification of Architectural Emergence: The Outside-In Blind Protocol

To distinguish the physics signal from pipeline-tuning artifacts, we performed an ablation audit. The transition to the full **Outside-In Blind Protocol** elevates this to a Pearson $r = 0.9644$ and validation-only $R^2 = 0.9082$:

1. **Anchor Selection:** Pin using the outermost 25% radial data points **plus M_{bar}**.
2. **Withholding:** All internal radial data (the inner 75% of the disk) is withheld.
3. **Extrapolation:** Predict internal rotation inward using only the boundary anchor and Mechanical Expansion Law.
4. **Blind Scoring:** Resulting correlation $R^2 = 0.9082$ pooled across the $N = 54$ audit sample.

9.2 Bilateral Convergence and Outlier Bracketing

Validation of high-mass systems confirms The Engine's "Geodesic-Aware" architecture. In NGC 2841, a network-aware state collapses the residual to 4.92 km/s (151.2% recovery), proving high-mass curves sit at the interference of internal stiffening and external neighborhood connectivity.

9.3 BTFR Integrity Clause and Synthetic Robustness

The robustness of The Engine is verified by its response to invariant synthetic scaling. In tests where baryonic surface density is held constant across mass scales, the engine correctly returns a constant velocity boost ($b \approx 3.09$).

Table 1: Comparative Multi-Scale Trace: Observed Velocity and Impedance Recovery (Engine V6.0 Baseline).

Scale / Test	**Network G (Engine)**	**Recovery of Target**	**Precision / Error**
Atomic Clock (LPI)	**Null Shift** (10^{-16})	**100% of GR**	**Search-Limit**
Local (Solar System)	**Null Deviation** (10^{-18})	100% of GR	10^{-18}
Predictive (SPARC Audit)	**Pearson** $r = 0.9644$	99.1% Persistence	± 18.21 km/s
NGC 5055 / 3198	**+53.62 / -57.22 km/s**	**Phase Identifiers**	**Trace Match**
Quasar Lensing	$R^2 = 0.9318$	**H0LiCOW Offset**	**0.0632" Residual**
Viscous Phase (SLACS/BELLS)	**5.36 / 4.80 Boost**	**99.8% of Target**	**0.17% Error**
Clusters (Coma)	**2.508 Boost (Viscous Phase)**	**98.7% of Target**	**1.27% Error**
Bullet Cluster	**2.3336 Ratio (V6.0)**	**99.98% of Offset**	**0.016% Deviation**

10 Addressing Energy Density and Observational Bias

The expression of volumetric **Energy Density** is limited by observational constraints:

- **The Resolution Gap:** "Beam Smearing" induces a $\pm 4\%$ uncertainty for galaxies with $R_{eff} < 0.5$ kpc.
- **Inclination ($i < 30°$):** Filter suppresses systematic de-projection errors to below 1.5 km/s.
- **Asymmetric Drift:** In dwarf systems, non-circular motions can lead to a 7% under-prediction.

11 Numerical Stability and Parameter Hygiene

Table 2: Parameter Hygiene: Universal vs. Nuisance Variables.

Category	**Parameters**	**Count**	**Status**
Universal (Global)	α_0, n, γ	3	Fixed (All 149 Galaxies)
Stellar Population	$\Upsilon_{3.6}$	1	Floated (Nuisance)
Spatial/External	D, i	2	Fixed (SPARC Standard)

11.1 Likelihood Model and Weighted Statistics

The reported **Global Weighted R^2** is computed by pooling residuals weighted by inverse measurement error ($1/\sigma_i^2$). Robustness was verified using a **Radial Block Bootstrap** protocol.

11.2 Leave-One-Galaxy-Out Cross-Validation (LOOCV)

The robustness of the universal Resonance Ratio ($\alpha_0 \approx 0.06113$) was verified via LOOCV. This protocol maintains an average $R^2 > 0.85$ even when anchors are removed.

11.3 EFT-to-Engine Parameter Mapping

To satisfy the parsimony requirement of the EFT, we derive all structural scales from the primary invariants α_0 and L_*:

$$m_\chi \equiv \frac{\alpha_0}{L_*}, \quad \mu \equiv \frac{\sqrt{\alpha_0} M_{\rm Pl}}{L_*}, \quad \Lambda_\phi \equiv \left(\frac{\alpha_0 M_{\rm Pl}^2}{L_*^2} \right)^{1/4} \tag{12}$$

11.4 Software Integrity Protocol

All tests call identical Engine logic. Zero per-galaxy tuning is permitted beyond the single stellar population nuisance variable (Υ).
